Introduction

Approximately 10% of vertebral artery (VA) aneurysms are fusiform and originate from the posterior inferior cerebellar artery (PICA) [1,2]. The ideal treatment for fusiform aneurysms is completely isolating them from the circulation while preserving flow to parent vessel branches. Fusiform aneurysms are treated surgically (proximal clip ligation, trapping, and microvascular bypass) or endovascularly (coil embolization, stenting, stent-assisted coiling, and flow diversion) [3–7].

The patient in this study was diagnosed with subarachnoid hemorrhage due to a ruptured right VA fusiform aneurysm originating from the PICA. Digital subtraction angiography confirmed that the PICA was supplied by collateral circulation via the ipsilateral posterior meningeal artery. Coil embolization of the ruptured VA fusiform aneurysm was performed. Generally, the PICA is involved in dissecting VA aneurysms, and a therapeutic strategy without reconstructive therapy could pose a significant risk of morbidity. However, this case, we could perform parent artery occlusion without bypass surgery or stenting because of the unusual collateral channel.

Case Report

A 60-year-old female patient presented to the emergency department with comatose mentation. Brain computed tomography angiography revealed subarachnoid hemorrhage due to a ruptured right vertebral artery (VA) fusiform aneurysm originating from the posterior inferior cerebellar artery (PICA). Subsequent digital subtraction angiography confirmed that the PICA was supplied by collateral circulation via the ipsilateral posterior meningeal artery. Coil embolization of the ruptured VA fusiform aneurysm was performed. Generally, the PICA is involved in dissecting VA aneurysms, and a therapeutic strategy without reconstructive therapy could pose a significant risk of morbidity. However, this case, we could perform parent artery occlusion without bypass surgery or stenting because of the unusual collateral channel.

PAO of the right VA and fusiform aneurysm was performed using coils. Follow-up DSA revealed aneurysm occlusion and PICA filling by collateral circulation via the ipsilateral PMA (Fig. 3). An external ventricular drain was performed after the endovascular treatment.

The patient recovered slowly, and she was able to return home with no focal neurological deficits after one month of rehabilitation. She has been capable of performing daily living activities since. One year postoperative, brain magnetic resonance imaging showed no interval change.

**Discussion**

Intracranial aneurysms can be classified according to their pathogenesis, shape, or etiology. Classification according to its form is the most used, and it can be divided into saccular and nonsaccular types. Fusiform aneurysms are nonsaccular and involve the vessel wall at a variable distance and can present different formation processes. The two principal causes of this type of aneurysm are dissection and atherosclerosis; disorders of collagen and elastin...
metabolism, by infections, very rarely by neoplastic invasion of the arterial wall and iatrogenesis are other origins of this vasculopathy [8]. Fusiform aneurysms represent about 3% to 13% of all intracranial aneurysms, and they are often observed at the vertebrobasilar system [8,9]. Approximately 10% of VA aneurysms are fusiform and originate from the PICA [1,2]. Fusiform aneurysms have different underlying pathologies, hemodynamics, anatomical distributions, natural histories, and treatments compared to the saccular variety [8]. The ideal treatment for fusiform aneurysms is completely isolating them from the circulation while preserving flow to parent vessel branches. Surgical treatments, proximal clip ligation, trapping, and microvascular bypass have classically been the method of choice for fusiform aneurysms. Some of these strategies achieve exclusion of the aneurysm from the circulation, while others depend on flow reversal to decrease the risk of future rupture. Endovascular treatments, including parent vessel coil embolization, stenting, stent-assisted coiling, and flow diversion, have recently emerged as alternatives to open surgery [3–7]. The patient in this study was hemodynamically unstable and therefore required urgent evaluation and treatment. DSA showed a VA fusiform aneurysm originating from the PICA, which was supplied by collateral circulation via the ipsilateral PMA. PVO of the right VA and fusiform aneurysm was performed using coils.

PMA arose from the third segment of the VA. After entering the skull, the PMA courses within the dura mater and supplies the occipital dura mater, falx cerebelli, tentorium cerebelli, and falx cerebri. Normally, there is no anastomosis between the PICA and PMA. However, four cases of PMA originating from the PICA have been reported [10,11] and one case of PICA originating from the PMA [12]. In the 12-mm to 20-mm embryo stages, the primitive cranial vessels differentiate into the external, dural, and cerebral vessels. Anastomoses exist among these three vascular systems prior to differentiation. Some anastomoses may present between the primitive vessels forming the PICA and the PMA and sometimes persist until adulthood [11]. However, the delayed development of collateral circulation from the PMA to the PICA has not been reported. We confirmed the presence of PMA through DSA. If the PICA is clogged, it can be life-threatening. However, in our case, effective embolization was possible. Despite being uncommon, PMA should be considered as a potential collateral channel to the PICA in therapeutic proximal PICA occlusion.

**Conclusion**

Generally, there is no anastomosis between the PICA and PMA. In a case like this, the PAO for a ruptured VA dissecting aneurysm involving the origin of the PICA is effective.
